

THE MACROBENTHIC FAUNA IN THE DUTCH SECTOR OF THE NORTH SEA IN 2002 AND A COMPARISON WITH PREVIOUS DATA

R. DAAN AND M. MULDER

This report presents data of the monitoring program of macrozoobenthos in the Dutch Continental Shelf (DCS) of the North Sea, a cooperation between the National Institute for Coastal and Marine Management/RIKZ (Rijkswaterstaat), the North Sea Directorate (Rijkswaterstaat) and the Department of Marine Ecology (NIOZ)

ROYAL NETHERLANDS INSTITUTE FOR SEA RESEARCH
Monitoring Macrozoobenthos of the North Sea

NIOZ-RAPPORT 2003-5

1. SUMMARY

In this report the results are presented of a macrobenthos survey on the Dutch Continental Shelf (DCS), carried out in spring 2002. The survey forms part of the 'Biological monitoring program of marine waters' (MON*BIOLOGIE, generally referred to as 'BIOMON') which was initiated by the National Institute for Coastal and Marine Management (RIKZ). The purpose of the program is to obtain insight into the year-to-year variations of the macrobenthic assemblages and to detect trend-like changes, that possibly indicate anthropogenic influences on the marine environment (e.g. eutrophication, pollution, beam-trawl fishery).

Within the framework of this project fieldwork is carried out every year in spring. In 2002 the 100 BIOMON stations were sampled in the period between March 11 and April 11. On the basis of the results collected in 2002 and previous years an analysis is made of the trends and fluctuations of some selected species and of basic community attributes over the period 1986-2002. The community attributes studied were the diversity, abundance and biomass of the total macrofauna and of the 4 major taxonomic groups. Temporal variation or trends were investigated separately for each of the four subareas in the DCS i.e. the Coastal, Offshore areas, Dogger Bank and Oyster Ground. The conclusions of this study can be summarized as follows:

1. The sediment composition in the four subareas was generally quite similar to that found in previous years. However there were a few exceptions. At station OFF 6, west of Texel, where a strong decline in the median grain size had been observed in 2001, this median grain size was back at its usual level in 2002. This indicates that, if any human activity had been responsible for the sediment change in 2001, recovery has taken place within one year. Further there are a few stations along the southern edge of the Frisian Front area that show high temporal variation in silt contents. Possibly the sediments are unstable here since depth may be critical here with respect to the effects of turbulence in bottom water on sediment composition. However, there is also one station in the deepest part of the Oyster Ground (>50m) where silt concentrations appear to be highly variable. Since sediments are expected to be stable here it is suggested that this variability is caused by local spatial differences in sediment composition rather than by temporal changes.
2. At the community level, there were a few changes compared to preceding years. At the Dogger Bank a slight decrease could be observed in diversity based on the Shannon Wiener Index. Further there was a rather strong decline in biomass, largely caused by the disappearance of large sea urchins (*Echinocardium cordatum*). Although usually only a few are found in the samples, these large specimens largely determine

the total biomass. In the Oyster Ground a slight but continuous increase could be observed in species richness (number of species per sample) and in biomass from 1996 onwards

3. At the Dogger Bank the sand star *Acrocnida brachiata*, the bivalve *Mysella bidentata* and the polychaete *Aricidea minuta*, three species that had shown a decline in preceding years occurred still in low numbers in 2002. A slight sign of recovery was observed in the polychaete *Nephtys cirrosa*. New to the Dogger Bank is the occurrence of the gastropod *Scaphander lignarius* and the bivalve *Gari costulata*. Within the DCS both species have been recorded only once. Both records are from the Oyster Ground.
4. In the Oyster Ground the recovery of the populations of the brittle star *Amphiura filiformis*, first observed in 2001, continued in 2002. Further the bivalve *Nucula nitidosa*, which had shown an increase in abundance since 1999, further increased to densities higher than ever within the BIOMON program. There were four species that have not been found before. The isopod *Bopyrus squillarum*, the amphipod *Dyopedos monacanthus* and the gastropods *Mangelia nebulosa* and *Scaphander lignarius* are new to the Oyster Ground. Some of them have been found during other research projects, but not within BIOMON. A few other species that had been found in 2000 or 2001 for the first time reoccurred in the samples in 2002.
5. In the Offshore area the sea urchin (*Echinocardium cordatum*) shows a slightly increasing trend from 1995 onwards, which continued in 2002, particularly in terms of biomass. The presence of relatively much large sea urchins was a major cause of the relatively high biomass values in the area in 2002. Recovery of populations of the gastropod *Euspira nitida* started in 2000 and continued in 2002. Three species are new within the BIOMON program. The polychaetes *Lagisca extenuata* and *Syllis gracilis* are probably new to the Dutch fauna. The bivalve *Striarca lactea* has been recorded from a few stations in other research programs.
6. In the Coastal area there seemed to be a tendency for an increase in the abundance of the amphipod *Urothoe poseidonis* and in the biomass of the sea urchin *Echinocardium cordatum*. The presence of large *E. cordatum* and/or the presence of banks of *Spisula subtruncata* or *Ensis americanus* were the cause of extremely high biomass values at a few stations. The polychaete *Nephtys assimilis*, a new species in 2001, was present now at 3 stations in the Coastal area. It seems that this species recently has colonized the whole DCS and that it has been successful in building up new populations.

2. SAMENVATTING

In dit rapport worden de resultaten gepresenteerd van een macrobenthos bemonstering die in 2002 werd uitgevoerd op het Nederlands Continentale Plat (NCP). De bemonstering vond plaats in het kader van het 'Biologische Monitoring Programma Zoute Wateren' (MON*BIOLOGIE, gewoonlijk aangeduid als 'BIOMON'), dat geïnitieerd is door het Rijksinstituut voor Kust en Zee. Met het project wordt beoogd inzicht te krijgen in de jaarlijkse fluctuaties van de macrobenthos gemeenschappen en vast te stellen of er op de langere termijn trendmatige veranderingen optreden. Dergelijke veranderingen zouden onder meer kunnen plaats vinden als gevolg van anthropogene activiteiten (bijv. eutrofiëring, verontreiniging, boomkorvisserij).

In het kader van dit project wordt jaarlijks veldonderzoek uitgevoerd in het voorjaar. In 2002 zijn de 100 BIOMON stations tussen 11 maart en 11 april bemonsterd. Aan de hand van de gegevens die in 2002 en voorgaande jaren zijn verzameld is een overzicht verkregen van de trends en fluctuaties bij een aantal geselecteerde soorten en een aantal kenmerken van de benthische gemeenschap als geheel over de periode 1986 - 2002. Deze set kenmerken bestaat uit de diversiteit, de dichtheid en biomassa van de totale fauna en de 4 belangrijkste taxa. Temporele variatie en trends zijn voor vier subgebieden van het NCP, de Kustzone, het Offshore gebied, de Doggersbank en de Oestergronden, afzonderlijk onderzocht. De conclusies van deze studie kunnen als volgt worden samengevat:

1. De sedimentsamenstelling in de vier subgebieden leek in het algemeen veel op die in vorige jaren. Op de afzonderlijke stations waren er enkele uitzonderingen op deze regel. Op station Off 6, ten westen van Texel, waar in 2001 een sterke afname in de mediane korrelgrootte werd geconstateerd, was deze mediane korrelgrootte in 2002 weer terug op het vroegere niveau. Dit wijst erop dat, als de verandering in sedimentsamenstelling veroorzaakt was door een of andere menselijke aktiviteit, herstel binnen een jaar heeft plaatsgevonden. Verder waren er enkele stations aan de zuidrand van het Friese Front gebied die van jaar op jaar grote variatie in slibgehalte vertoonden. Mogelijk zijn de sedimenten hier instabiel omdat de diepte hier kritisch is met betrekking tot de effekten die turbulentie in het bodemwater kunnen hebben op de sedimentsamenstelling. Er is echter ook een station in het diepste deel van de Oestergronden (>50m) waar de slibconcentraties zeer variabel blijken te zijn. Aangezien de sedimenten hier vermoedelijk wel stabiel zijn, is de variatie eerder te verklaren uit lokale ruimtelijke verschillen dan uit veranderingen in de loop van de tijd.

2. Op community niveau waren er enkele kleine veranderingen ten opzichte van de voorgaande jaren. Op de Doggersbank werd op basis van de Shannon Wiener Index een lichte afname gevonden in diversiteit. Verder was er een sterke afname in biomassa, met name door het ontbreken van grote hartegeels (*Echinocardium cordatum*). Hoewel er gewoonlijk maar een paar worden gevonden in de monsters, maken deze grote exemplaren vaak het overgrote deel van de biomassa uit. In de Oestergronden werd vanaf 1996 een lichte maar continue stijging waargenomen in soortenrijkdom (aantal soorten per monster) en in biomassa.
3. Op de Doggersbank kwamen 3 soorten, die in voorgaande jaren een achteruitgang hadden doorgemaakt, nog steeds in lage dichtheden voor. Het gaat hier om de slangster *Acrocnida brachiata*, de bivalve *Mysella bidentata* en de polychaet *Aricidea minuta*. Een licht teken van herstel was er bij de polychaet *Nephtys cirrosa*. Nieuw voor de Doggersbank zijn de gastropode *Scaphander lignarius* en de bivalve *Gari costulata*. Voor het NCP konden we voor beide soorten maar een eerdere melding vinden. Beide zijn eenmaal aangetroffen in de Oestergronden.
4. In de Oestergronden zette het herstel van de slangster *Amphiura filiformis*, dat zich in 2001 had aangediend, zich in 2002 voort. De bivalve *Nucula nitidosa*, die vanaf 1999 in aantal is toegenomen, nam verder toe tot dichtheden die in het BIOMON programma nog niet eerder zijn waargenomen. Vier soorten werden nog niet eerder gevonden. De isopode *Bopyrus squillarum*, de amphiipode *Dyopedos nonacanthus* en de gastropoden *Mangelia nebulosa* en *Scaphander lignarius* zijn nieuw voor de Oestergronden. Sommige zijn wel eens tijdens een ander project gevonden, maar nooit binnen het BIOMON-programma. Sommige soorten die in 2000 of 2001 voor het eerst werden aangetroffen kwamen opnieuw in de monsters voor.
5. In het Offshore gebied laat de hartegeel (*Echinocardium cordatum*) vanaf 1995 een licht toenemende trend zien, met name wat betreft biomassa. Deze trend zette zich voort in 2002. De aanwezigheid van relatief veel grote hartegeels was er de oorzaak van dat het gemiddelde biomassagetel hoog was voor het Offshore gebied. Herstel van populaties van de gastropode *Euspira nitida* deed zich voor vanaf 2000 en zette zich voort in 2002. Drie soorten zijn nieuw binnen het BIOMON programma. De polychaeten *Lagisca extenuata* en *Syllis gracilis* zijn vermoedelijk nieuw voor de Nederlandse fauna. De bivalve *Striarca lactea* is eerder al wel op enkele stations binnen andere onderzoeksprogramma's gevonden.
6. In de kustzone was er een tendens van toename in de aantallen van de amphiipode *Urothoe poseidonis* en in de biomassa van de hartegeel *Echinocardium cordatum*. De aanwezigheid van grote hartegeels en/of de aanwezigheid van banken van *Spisula subtruncata* of *Ensis americanus* was de oorzaak van extreem hoge biomassagetallen

Monitoring macrozoobenthos North Sea 2002

op enkele stations. De polychaet *Nephtys assimilis*, in 2001 nog een nieuwe soort, was nu aanwezig op 3 stations in de kustzone. Het lijkt erop dat deze soort recent het gehele NCP met succes heeft gekoloniseerd.

3. INTRODUCTION

In 1989 the BIOlogical MONitoring program of marine waters (project MON* BIOLOGIE) was started with the goal to study the temporal variation of the marine ecosystems on the Dutch Continental Shelf (DCS) including the Wadden Sea and the Delta area. It is an initiative of the National Institute for Coastal and Marine Management (RIKZ) of Rijkswaterstaat in association with several Dutch institutes (Yland, 1995). The biological monitoring program comprises besides the macrobenthos also plankton, fish, seagrass, hard substrate populations, seabirds and mammals.

This report presents the data collected during the macrobenthos survey carried out in spring 2002. Further the results of the 2002 survey are compared with the BIOMON data collected in previous years (1991-2002) and those obtained during the ICES North Sea Benthos Survey (ICES-NSBS, 1986) and the MILZON-BENTHOS program (1988-1993). In 1990 a pilot study of the BIOMON project was carried out at 7 locations on the DCS and the results are also included in the data base.

The aim of the BIOMON program is to obtain insight in the spatial and temporal variation in the composition of the macrobenthos and to detect possible trendlike changes on the DCS as a whole or in parts of it. During the first years (1991-1994) there were 25 stations located along 5 transects perpendicular to the Dutch coast. At these stations 5 replicate boxcore samples were collected each year. Although in this way a rather detailed picture was obtained of the fauna composition at each of these stations, it was argued that (changes in) the macrobenthos composition of the DCS as a whole could better be studied by spreading the sampling effort over a larger number of stations. Therefore, from 1995 onwards the sampling strategy changed and each year 100 stations were visited, that were selected according to a stratified random sampling design in each of the 4 subareas of the DCS, i.e. Dogger Bank, Oyster Ground, Offshore area and Coastal area (Fig. 1). The number of stations within each subarea was proportional to its surface area. At each station only one sample was taken. The 100 stations that were selected include the 25 original BIOMON stations. The selection procedure is described in more detail by Essink (1995) and Holtmann *et al.* (1996).

The analysis of the results obtained in previous years (Daan & Mulder, 2002) has shown that there were generally no clear trends at the community level (faunal density, biomass, biodiversity parameters) in the 4 subareas. However, in most subareas there seemed to be a slight decrease in the contribution of molluscs to the total benthic biomass. At the species level there was a clear downward trend in the abundance of the brittle star *Amphiura filiformis* in the Oyster Ground from 1993 onwards. Particularly at

the Frisian Front a dramatic decrease was observed in the abundance of this species. Further there was a decrease in the abundance of the polychaete *Nephtys cirrosa* and the gastropod *Euspira nitida* in the Offshore area and the Coastal area. The latter species also decreased at the Dogger Bank. The new data will show to what extent the apparent trends observed in previous years continued in 2002.

4. MATERIAL AND METHODS

To ensure that any changes that are observed are not due to methodological differences, the procedures for sampling and processing the fauna samples are standardized (Essink, 1991) and have remained unaltered since the beginning of the monitoring project in 1991.

4.1. SAMPLING

In 2002 the BIOMON stations were sampled in the period March 11 to April 11. Most stations have a water depth >5 m and were visited with the RV Mitra or the RV Rotterdam (North Sea Directorate, RWS). However, two stations in the Coastal subarea with a water depth less than 10 m, viz. COA 13 & 14 were sampled with the RV. Delta.

Fig. 1 shows the positions of the stations . The exact geographical positions of the 100 stations, together with the delta codes and selected abiotic characteristics (depth/sediment) of the stations are summarized in Table 1a/b. More general information about the cruise carried out with the vessels and the weather conditions during this part of the survey in 2002 can be found in the cruise report of Rijkswaterstaat (Anonymous, 2002).

4.2. SAMPLE TREATMENTS

At each station two boxcore samples (0.078 m^2 , minimal depth 15 cm) were taken. One of the samples was used for sediment analysis and the other sample was washed through a sieve with round holes (1 mm) to collect the macrobenthic fauna. For sediment analysis 2 subsamples (3.4 cm Ø, depth 10 cm) were pooled and immediately stored at -20°C. The residue of the macrobenthos samples was preserved in a borax-buffered solution of 4-6 % formaldehyde in seawater and stored at room temperature.

In the laboratory the macrobenthos samples were stained with rose-bengal and washed over a set of nested sieves with 0.7 mm as the smallest mesh size to facilitate

sorting. The macrofauna was identified to species level, except for some notoriously difficult taxa such as anthozoans, phoronids, priapulids and nemerteans, and subsequently counted. Juvenile macrobenthic animals which because of their size could not be identified to species level were recorded on higher taxonomic levels, usually the genus level. Sizes (nearest 0.5 mm) were recorded for most molluscs and echinoderms.

4.3. ASHFREE DRY WEIGHT

The ash-free dry weight (AFDW) of the different taxa was determined in one of the following ways:

- Molluscs and echinoids:

By means of length-AFDW relationships of the form $W=a*L^b$ ($W=AFDW$ in g and $L=$ length in mm).

- Polychaetes, other worms, larger crustaceans and ophiuroids:

Indirectly, by converting the (blotted) wet weight into AFDW by means of conversion factors provided by Rumohr *et al.* (1987) and Ricciardi & Bourget (1998). Wet weights were measured with a Mettler PJ300 balance to the nearest mg.

- Remaining taxa:

Directly, by drying a sample at 60 °C for at least 60 hours and subsequently incinerating at 520 °C for 2 hours (Duineveld & Witte, 1987).

Small molluscs, amphipods and cumaceans were assigned an average individual AFDW of 0.2-0.5 mg. The same value is used by Holtmann & Groenewold (1992; 1994) in their analysis of macrobenthos from the MILZON-BENTHOS project in the southern North Sea between 1991 and 1993. This estimated individual weight is based on previous determinations of the AFDW of the taxa in question (Duineveld; Holtmann, unpubl.).

4.4. STATISTICS

In addition to the density (ind./m²) and biomass (g AFDW/m²), the diversity of each macrobenthos sample was calculated. In the literature a suit of biodiversity indices have been used to identify possible changes of the benthic fauna (Hill, 1973; Peterson, 1977; Pearson & Rosenberg, 1978; Harper & Hawksworth, 1994). In this report, we used three indices each representing a different aspect of the faunal diversity. The species richness

($Hill_0$) stands for the number of species per boxcore sample and is the simplest index. The other two indices, the Shannon-Wiener index (H') (Shannon & Weaver, 1949) and the Simpson index (D) for dominance (Simpson, 1949), are based on the proportional abundances of the individual species in the samples. The Simpson index is sensitive to the abundance only of the more plentiful species and can therefore be regarded as a measure of dominance (Hill, 1973). A high value for Simpkins index means low diversity, whereas a high value for the $Hill_0$ or Shannon-Wiener index indicates high diversity.

4.5. SEDIMENT ANALYSIS

At each station shown in Fig. 1, two subsamples were taken from an intact boxcore sample and subsequently pooled for laboratory analysis of the sediment composition (*e.g.* grain size, content of calcium carbonate). The grain size was analyzed with a Malvern Particle Sizer by the laboratory of the National Institute for Coastal and Marine Management (RIKZ, Middelburg). Two parameters were derived from the grain size data: the median grain size (μm) and the percentage (by weight) of mud. We here define mud as the total fraction mineral particles $< 63 \mu\text{m}$. However, for comparison with previous years we also calculated the fraction $16\text{-}63 \mu\text{m}$.

Sediment types were classified on the basis of the median grain size as follows:

Characterization of the sediment type according to
the median grain size (after Gullentops *et al.*, 1977).

$< 175 \mu\text{m}$	Very fine sand
$175\text{ - }250 \mu\text{m}$	Fine sand
$250\text{ - }300 \mu\text{m}$	Medium-fine sand
$300\text{ - }350 \mu\text{m}$	Medium-coarse sand
$> 350 \mu\text{m}$	Coarse sand

5. RESULTS AND DISCUSSION

5.1. SEDIMENT COMPOSITION

The median grain size and silt content of the sediment at the stations sampled are listed in Table 1. Spatial and temporal patterns are illustrated in Fig. 2, 3 and 4.

The spatial pattern in the sediment composition in 2002 was quite similar to that in the preceding years. A look at the mean median grain size in the 4 subareas between 1995 and 2002 (Fig. 4) shows that the grain size is not only very stable, but that the variation around the mean is extremely small. Also at most of the individual stations the median grain size did not substantially change compared to preceding years. A comparison between the values measured in 2002 (Fig. 2) and those found in previous years shows that in more than 80% the size class did not change and that in most of the other cases the difference was not more than 1 size class. There are, however, two exceptions. At station OFF 2, north of Schiermonnikoog, the median grain size was about 340 µm in 1997 and 1999, but substantially lower, about 210 µm, in the other years. In previous reports we already suggested that OFF 2 is situated at a sharp local gradient where the sediment changes from fine sand into medium-coarse sand within a short distance. As a consequence, small year to year differences in sampling position could result in rather strong differences in sediment composition. In 2002 the median grain size was 206 µm, which is within the range of values found in most of the preceding years. At station OFF 6, west of Texel, a steep decline in the median grain size was observed in 2001. Here the values had dropped from 280 – 320 µm in the period 1996 – 2000 to 200 µm in 2001. It has been suggested that a local physical disturbance, possibly by human activities, could have occurred at this station, leading to a selective disappearance of the larger size fractions in the sediment. In 2002 the median grain size at OFF 6 was 310 µm, so back at the level of preceding years. This could indicate that relocation of sediments by bottom currents has lead to recovery of the natural sediment composition within one year.

The distribution of silt in the sediment also showed the same spatial pattern as in the preceding years (Fig. 3). In 2001 there was one station where a substantial difference was found in the silt content compared to 1999 and 2000. This was station OYS 8, at the southern edge of the Frisian Front. The silt content at this station had dropped from 22 and 28 % in the preceding years to less than 9 % in 2001. In 2002 we found an intermediate value of 17%. The station is located in an area with a sharp north-south gradient in silt concentrations which is linked up with a relatively steep depth gradient. This means that a small difference in positioning possibly could have a strong effect on the silt content measured. Moreover, silt contents may be unstable at this station, since the

depth is between 30 and 40 m and therefore critical with respect to sedimentation and resuspension of silt. In 2002 there were 3 Oyster Ground stations that showed silt concentrations that were substantially lower than in 2001. These stations were OYS 11, 20 and 24, and showed declines from 38 to 15 %, 18 to 7 % and 34 to 8 % respectively. However, the silt contents found in 2002 were not extremely low when compared to the values found in the period before 2001 (see the text table below).

Text table: Silt contents (%) at 3 stations in the Oyster Ground.

	silt fraction 0 – 63 µm							
year	1995	1996	1997	1998	1999	2000	2001	2002
OYS 11	?	?	?	?	23.6	28.5	38.2	15.4
OYS 24	?	?	?	?	12.7	17.6	33.7	8.0
OYS 20	?	?	?	?	16.2	5.8	18.0	6.8

	silt fraction 16 - 63 µm							
year	1995	1996	1997	1998	1999	2000	2001	2002
OYS 11	14.8	15.3	25	22	9.5	18.0	27.0	6.4
OYS 24	4.0	4.9	2	7	6.0	8.7	26.7	2.5
OYS 20	1.8	5.7	7	0	9.1	0.0	9.2	0.9

Values for the total 0 – 63 µm fraction have been determined only in the most recent years, but values for the 16 – 63 µm fraction are available from 1995 onwards. At each of the 3 stations the silt concentrations appear to be highly variable. The fluctuations do not indicate a consistent temporal trend. Only for station OYS 11 the values were the lowest in 2002 for both silt fractions, but still of the same order as those found in 1999. At station OYS 24 the 0 – 63 µm fraction was the lowest in 2002, but also of the same order as in 1999. The 16 – 63 µm fraction was within the range of values found in previous years. At OYS 20 both fractions were within the range of values found in previous years.

The 3 stations mentioned are all located at the edge of the Oyster Ground area. OYS 11 and 24 lie near the southern edge of the area, close to the 30 m depth contour. In view of the limited depth it is conceivable that silt concentrations are unstable here, which could explain the high variability observed. Nevertheless, high spatial variability can not be excluded as an explaining factor. Station OYS 20 is situated near the western edge of the Oyster Ground , close to the Klaverbank. In this area relatively steep depth gradients do occur too. However, the water depth at OYS 20 is over 50 m and so deep enough to expect silt concentrations that are stable over time. We therefore assume that the strong year to year differences reflect local spatial variability, rather than temporal variability.

5.2. DISTRIBUTION OF THE MACROBENTHIC FAUNA IN 2002

5.2.1 Diversity, density and biomass

A total number of 207 species/taxa were identified in the 100 boxcore samples in 2002, including 3 that were identified to genus level only (most juveniles) and 9 higher taxa (identified to family level or higher). The total number of taxa is within the range of previous years (181 – 231). The distribution of the species over the stations (presence/absence) and the scientific names are given in Appendix-1. The basic data on macrobenthic abundance, biomass and diversity are listed in Appendix-2.

The mean number of species per sample (Hill 0) was the highest on the Dogger Bank and in the Oyster Ground and the lowest in the coastal and offshore area (Table 2, Fig. 5,8). There is an overall pattern of high species richness in the North and low species richness in the south. In the Oyster Ground there was a tendency for a slight increase in species richness from 1996 onwards. In the other subareas no clear long term trend could be observed in species richness. In the Offshore area there were four stations with a relatively rich fauna. The samples collected at OFF 1, 4, 5 and 33 all contained more than 30 species. These stations are exactly the same that showed a rich fauna in 2001 too. A look at the long term trend at these stations shows that species richness was generally low (10 to 20 species per box) before 1995. In 1995 peak values were found of about 30 species per box. Thereafter species richness was medium to low (15 to 25 species per box) up to 1999. From 2000 onwards there was a continuous increase to values beyond 30 species per box. This trend was more or less the same at each of the 4 stations.

The Shannon Wiener diversity was more or less the same at the Dogger Bank, the Oyster Ground and the Offshore area. For Simpson's dominance holds the same (Table 2, Fig. 9,10). Diversity had slightly decreased at the Dogger Bank compared to previous years, whereas it remained the same in the Oyster Ground and the Offshore area. Low Shannon Wiener diversity was found in the Coastal area whereas Simpson's dominance was high here. This means that the fauna in the samples was generally dominated by one or two abundant species. Species that were sometimes dominant in the samples are the crustacean *Urothoe poseidonis*, the polychaete *Spiophanes bombyx* and the molluscs *Ensis americanus*, *Mysella bidentata*, *Spisula subtruncata* and *Tellina fabula*.

The mean fauna density was as usual the lowest in the offshore area and the highest in the Oyster Ground (Table 2, Fig. 6.). At the Dogger Bank and in the Offshore area polychaetes were the most abundant group. In the Coastal area molluscs dominated. In the Oyster Ground the numbers were more or less equally distributed over the different

taxonomic groups, with a slight predominance of echinoderms and molluscs. There were no trendlike changes in fauna abundance (Fig. 11).

Biomass values at the Dogger Bank were clearly lower than in 2001 (Table 2, Fig. 12). Particularly the share of echinoderms and polychaetes had decreased. It is not clear what can have been the cause of the decrease, since in the Oyster Ground we saw a clear increase of the biomass compared to 2001 and in the Offshore and Coastal areas there was hardly any change. This indicates there can not be an effect of a (small) difference in the timing of sampling between both years. There does not seem to be a trendlike change, although in the Oyster Ground we can see a slight but continuous increase of biomass from 1997 onwards. The highest mean biomass, but also the strongest variation was found again in the coastal area (Fig. 7). As in previous years the peak values found at some stations in the coastal area were generally caused by dense populations of the mollusc *Spisula subtruncata* or by *Ensis americanus*.

With respect to the share of the different taxonomic groups to the total biomass there was no change in the Oyster Ground compared to the preceding year. Biomass of all major groups increased in this area. Also in the Offshore and Coastal areas there was no substantial change in the share of the different groups. The share of these groups remained more or less the same both in an absolute sense as in a relative sense. At the Dogger Bank the situation was different. Here mollusc biomass was, in an absolute sense, the same as in 2001, but since polychaete and echinoderm biomass decreased, the share of mollusc biomass increased considerably.

5.2.2. TEMPORAL VARIATION IN DENSITY AND BIOMASS OF INDIVIDUAL SPECIES

Figs. 13-16 illustrate the temporal variation in density or biomass of a number of individual species in the 4 subareas during the period 1986-2002.

Dogger Bank (Fig. 13a-c)

On the Dogger Bank there were a few species that showed a remarkable decrease in 2001. The sand star *Acrocnida brachiata*, the bivalve *Mysella bidentata* and the polychaetes *Nephtys cirrosa* and *Aricidea minuta* occurred in lower densities than ever in the nineties. Of these species *A. brachiata* and *M. bidentata* did still occur in low densities in 2002, whereas *A. Minuta* was still absent. A slight sign of recovery was only observed in *N. cirrosa*. The gastropod *Euspira nitida*, which had shown an increase from 1999 onwards remained stable in 2002.

In fig. 13b a graph is shown of the temporal development of a combination of 2 species, *Magelona mirabilis* and *M. johnstoni*, which showed stable densities in 2002. In

previous years we only distinguished *M. mirabilis*. However, recently it has become clear that in fact *M. mirabilis* comprises two morphologically similar species, *M. mirabilis* s.s. and *M. johnstoni* (Fiege *et al.*, 2000). For reasons of comparability with previous data we plotted here the density of the combination of the two species. A plot of *M. mirabilis* s.s. in sequel of the preceding development of *M. mirabilis* would erroneously suggest that the species had strongly declined in 2002, since *M. johnstoni* appeared to be 10 times as abundant as *M. mirabilis* s.s..

A species that is new to the Dogger Bank is the gastropod *Scaphander lignarius*. In the North Sea this species is usually found at higher latitudes. For the Dutch sector we found only one record: in 1986 one specimen has been found in the north western part of the Oyster Ground (de Wilde & Duineveld, 1988). Another species that is also new to the Dogger Bank is the bivalve *Gari costulata*. This species was on the DCS found for the first time in 2001, but then in the Oyster Ground (Daan & Mulder, 2002). In 2002 it was found at 3 stations at the Dogger Bank.

The number of species found at the Dogger Bank in 2002 (70) was well within the range of values found in previous years (66 – 87). Also the total fauna density was similar to that in previous years. Nevertheless, the total biomass appeared to be extremely low. A major cause is that in previous years always a few large sea urchins (*Echinocardium cordatum*) occurred in the samples. A few of those specimens usually account for the major part of the total biomass. In 2002 such large specimens were not found, which must have been a substantial cause of the decline in biomass.

Oyster Ground (Fig. 14a-c)

Most species in the Oyster Ground showed more or less stable densities compared to the preceding year or just a slight increase. This holds also for one of the most abundant species in the Oyster Ground, the brittle star *Amphiura filiformis*. Nevertheless, at the Frisian Front the densities of this species were still low compared to the numbers that were found here in the early nineties. The bivalve *Nucula nitidosa*, which had shown an increase in abundance since 1999, further increased in the Oyster Ground to densities that have not been found before.

There was one species that has not been found before during the BIOMON program and it is probably new to the Dutch fauna. It is the isopod *Bopyrus squillarum*, which lives as a parasite in the gills of shrimps of the genus *Palaemon* (Huwe, 1977). Although there are a few records of the species *Palaemon elegans* for the North Sea (Bergman *et al.*, 1998), a host of this genus was not found in the sample. Possibly *B. squillarum* can also live on other crustacean species like *Callianassa subterranea* or

Upogebia deltaura, which were present in the sample. According to Huwae (1977) there is only one doubtful record of *B. squillarum* from the Dutch coast.

Three other species are new to the BIOMON program. The amphipod *Dyopedos monacanthus* has been found during the synoptic mapping in 1986 (de Wilde & Duineveld, 1988) and during the MILZON program in 1991 (Holtmann & Groenewold, 1992). Empty shells of the gastropod *Mangelia nebula* have been found several times before in the Oyster Ground, but this time a living individual was captured. Bergman et al. (1998) found this species in 1997 in a dredge haul at one station in the northern Oyster Ground. Finally, like at the Dogger Bank, we found the gastropod *Scaphander lignarius* also at one station in the Oyster Ground. Together with the record of de Wilde & Duineveld (1988) there are 3 stations where the species has been found till now, all in the north western part of the DCS.

Finally there is a number of species that have been found in 2000 or 2001 for the first time and that reappeared in one or more samples in 2002. The gastropods *Retusa umbilicata* and *Ondina divisa*, new in 2000, were found at OYS 15 and OYS 36 respectively in 2002. The bivalves *Semicycina nitida* and *Telliniya ferruginosa* that have been found in 2001 for the first time did occur on 5 and 3 stations respectively in 2002. The polychaete *Nephtys assimilis*, also a new species in 2001, was found at 3 stations in the Oyster Ground, but also at a number of stations in the Offshore and Coastal areas. The latter species was known only from the Loswal dumpsite west of the Hague (de Kluijver & van Nieuwenhoven, 1998). It seems that the species mentioned has colonized the DCS recently and that it has been successful in building up new populations.

Species richness was in the Oyster Ground, in terms of mean number of species per sample, higher than ever before during the BIOMON program, i.e. 33.5 species per sample compared to 24 to 30 species in the period 1995 – 2001. It seems tempting to explain this increase by the success of the new colonizers mentioned above. However, in spite of their success these species are still too sparsely represented in the samples to contribute substantially to this measure of species richness. The limited role of these species is also reflected in the total number of species in the area (162) which was well within the range of values found in previous years (135 to 178). Apparently there was a number of species that have been found now and then in previous years, but were not found in 2002. The absence of the latter species apparently neutralized the presence of the new species, so that the diversity did not change.

Offshore area (Fig. 15a-c)

The plots of the population densities of 11 of the commonest species show that most populations fluctuate around an average level, without showing a clear temporal trend. However a few species show a more or less consistent pattern. The sea urchin *Echinocardium cordatum* shows a slight increasing trend from 1995 onwards. This trend continued in 2002, particularly in terms of biomass. Populations of the gastropod *Euspira nitida* reached a low in 1999, but started recovery in 2000. This recovery continued in 2001 and 2002.

Usually the Offshore area has the poorest benthic fauna. Total fauna densities, biomass and diversity are generally the lowest in this area. In 2002 the total fauna density was again by far the lowest here (Tab. 2). However, the biomass was not particularly low and at a level that is usually found in the Oyster Ground. The high biomass values are mainly due to the presence of relatively much large sea urchins (*Echinocardium cordatum*). Also the number of species per sample was relatively high and Shannon Wiener diversity was at a similar level as in the Oyster Ground and at the Dogger bank.

A particular rich station was again OFF 33, west of IJmuiden. After values of about 20 species per sample in the second half of the nineties, this number increased to 32 in 2000, 35 in 2001 and 39 in 2002. Remarkable elements in the fauna were the brittle star *Amphiura filiformis* (usually only occurring in the Oyster Ground), the gastropods *Alvania lactea* and *Tornus subcarinatus*, an unidentified polyplacophoran and the polychaete *Syllis gracilis*. Since some of the species at this station are dwellers of solid substrate, it has been suggested that the sample could have been taken close to a ship's wreck. This was verified by J. Kamphuis (North Sea Directorate) and he found out that there is a wreck indeed at a distance of 450 m in southeastern direction (205°). This is not in the immediate vicinity of the sampling station, but since the prevailing current is in northeastern direction it can not be excluded that faunal elements from the wreck are sometimes transported in this direction by bottom currents.

There were 3 species that have not been found before during the BIOMON program. For the polychaetes *Lagisca extenuata* and *Syllis gracilis* we could not find any record from the DCS, so probably these species are new to the Dutch fauna. The bivalve *Striarca lactea* is not new because it has been recorded from a few stations on the DCS in other research programs, e.g. one station in the Offshore area near a gas platform (Daan & Mulder, 1994). The polychaete *Nephtys assimilis*, a new species in 2001, was now found at 3 stations in the Offshore area.

Coastal area (Fig. 16a-c)

Among the most common species in the Coastal area there were two species, *Euspira nitida* and *Tellina fabula*, that had shown an increase in 2001. Both species did not further increase in 2002 but remained at a stable level. This holds also for most of the other common species. However, there seems to be a tendency for an increase in the abundance of the amphipod *Urothoe poseidonis* and in the biomass of the sea urchin *Echinocardium cordatum* from 1998 onwards. The densities of the polychaete *Nephtys cirrosa* were still at a low level. After a steep decline in 1996 this species has never reached its former densities. *N. cirrosa* is a species of sandy sediments and also occurs at the Dogger Bank and the Offshore area. Since the species showed low densities also at the Dogger Bank and, to a lesser extent, in the Offshore area, there seems to be a trend that covers the whole DCS.

Like in previous years, high biomass values were found at stations where banks of bivalves (*Spisula subtruncata* and/or *Ensis americanus*) occurred and/or where large sea urchins (*Echinocardium cordatum*) were found. Particularly high values occurred at the stations COA 2, 3, 8 and 9. At stations where such banks were absent, the biomass values were generally low.

The polychaete *Nephtys assimilis*, a new species in 2001 and already mentioned for the Oyster Ground and Offshore area, was also present at 3 stations in the Coastal area. Finally we found a small bivalve species which we identified as 'Sphenia binghami'. We use quotes here since it is not sure whether the identification is correct or not. It is possible that it is in fact a juvenile *Mya truncata*. This has to be verified by comparing it to specimens present in a scientific collection.

6. Acknowledgements

The monitoring program is initiated by the National Institute for Coastal and Marine Management (RIKZ), with J. de Vlas and M. Latuhihin as project leaders, and is carried out in cooperation with the North Sea Directorate (DNZ) and the department of Marine Ecology of the NIOZ. We want to thank the captain and crew on board of the RV Mitra, the RV Rotterdam and RV Delta for their assistance during the fieldwork, W. Schreurs and G. den Hartog (RIKZ Middelburg) for the analysis of the sediment samples, J. de Vlas for critically reading the original manuscript, M. van Arkel for his contribution in the organization and H. Hobbelink for the cover design.
